Acknowledgement

The author wishes to thank several people. I would like to thank Drs. Peter Moon, Ellen Hahn for all their help and direction, Dr. Al Best for the statistical analysis, and Dr. David Pashley for allowing the use of his fluid filtration apparatus. Additionally, I wish to thank Dr. John T. Marley, who provided methodological guidance, and spent countless hours working with me on this project. Specifically, I would like to thank Dr. Gary Hartwell for his unending leadership, compassion, mentoring and support during the residency. I would also like to thank my wife Lillian, and my family for their love, support and patience. Finally, I give thanks to God for restoring my health, and allowing me the strength to complete this project.

Abstract

THE EFFECT OF CHLORHEXIDINE GLUCONATE AS AN ENDODONTIC IRRIGANT ON THE APICAL SEAL: LONG-TERM RESULTS

By David B. Ferguson, D.D.S.

A thesis submitted in partial fulfillment of the requirements for the degree of Master of Science at Virginia Commonwealth University

Virginia Commonwealth University, 2002

Chairman and Professor, Department of Endodontics

The purpose of this study was to determine whether chlorhexidine gluconate (0.12%), used as an endodontic irrigating solution would affect the apical seal of three root canal cements. One hundred extracted human single-canal teeth were divided into 9 experimental groups of 10 teeth each, in addition to a positive and negative control group of 5 teeth each. The teeth were decoronated at the level of the cementoenamel junction, accessed, instrumented to a Master Apical File #50, irrigated with either sterile saline, 5.25% NaOCl or 0.12% chlorhexidine gluconate, and dried using paper points. Obturation was accomplished using lateral condensation and one of three endodontic sealers: Roth’s 811, AH26, or Sealapex. Post-obturation apical leakage was measured at 270- and 360-day observation periods using the fluid filtration method. Using the mixed-model repeated-measures ANOVA test with Tukey’s HSD multiple comparison
procedure, the results showed the saline-Sealapex combination had significantly more
leakage (p<0.05) than either the Peridex-Sealapex or saline-Roth’s combinations at 270
days. No other significant differences were noted between any sealer-irrigant
combination at 270 days. The saline-Sealapex combination had significantly more
leakage than the saline-Roth’s combination at 360 days. No other significant differences
were noted at 360 days. Under the conditions of this study, chlorhexidine gluconate
irrigant did not adversely affect the apical seal of three root canal cements at 270 and 360
days.
Introduction

One of the most important objectives in nonsurgical endodontic therapy is to disinfect the entire root canal system before obturation of the canals. Sodium hypochlorite has long been the irrigant of choice because of its antimicrobial activity and tissue dissolving ability, but it has been found to cause severe inflammatory reactions when placed in contact with vital tissues (1-2).

Chlorhexidine gluconate is recognized as being an effective oral antimicrobial agent and is routinely used in periodontal therapy and for caries prevention (3). Chlorhexidine, in the form of a salt, has been used since the 1950’s as an oral antiseptic in mouthwash, toothpaste, and chewing gum (4). Chlorhexidine has been found to have broad-spectrum antimicrobial action (5), substantivity (4,6), and a relative absence of toxicity (5). These properties have led to the suggestion that this solution may have some potential use as an irrigant in endodontics. A search of the literature failed to reveal any studies that have investigated what effect chlorhexidine may have on endodontic cements and their ability to seal the root canal system.

The assessment of the sealing ability of root canal obturation materials has been investigated by numerous investigators (7,8). The most widely used technique to evaluate apical seal has been the measurement of linear dye penetration (9). Studies have
shown that entrapment of air bubbles may exert a negative impact on the dye leakage and have suggested the use of a positive pressure system to obtain a more realistic result (10). The purpose of this study was to evaluate whether chlorhexidine gluconate (0.12%), when used as an endodontic irrigant, would affect the seal obtained when using three different endodontic cements. This study reports the long-term results obtained at 270- and 360-day observation periods. The short-term results published in a previous study by the same authors revealed no significant differences between irrigants, and sealers at 90- and 180-day observation periods (11).
Materials and Methods

One hundred extracted human single-rooted teeth were used in this investigation. The teeth were randomly divided into nine experimental groups of ten teeth each and a positive and negative control group of five teeth each. All procedures were conducted by two operators. All instrumentation procedures were performed by one investigator and all obturation procedures by the other. This technique provided continuity of treatment throughout each section of the experiment. The teeth were stored in sterile saline (0.9% sodium chloride) before the initiation of the experiment. The teeth were decoronated at the level of the cementoenamel junction using a carborundum disk, and the root surfaces were debrided of tissue as needed.

The working lengths were determined by placing a #10 file into the root canal until it was visible at the apical foramen and subtracting 1 mm from that length. The canals were prepared in a step-back manner using Flexofiles (Dentsply/Caulk, Milford, DE) and Gates Glidden drills (Moyco Industries Inc./Union Broach Division, NY, NY) to a master apical file size of #50. Three milliliters of irrigant was used after every change of Gates Glidden drill or endodontic file. Three different irrigating solutions were used in this study. Teeth in groups 1 to 3 were irrigated using sterile saline (0.9% sodium chloride, Baxter Healthcare Corporation Deerfield, IL), teeth in groups 4 to 6 were irrigated using 5.25% sodium hypochlorite (Clorox, Oakland, CA), and teeth in groups 7 to 9 were
irrigated using 0.12% chlorhexidine gluconate (Peridex, Zila Pharmaceuticals, Inc, Cincinnati, OH). Both control groups were irrigated using sterile saline.

After instrumentation, the root canals were dried with paper points (Dentsply/Caulk), and a #50 master gutta-percha cone (Hygenic Corporation, Akron, OH) was fitted to working length. A #10 file was also passed through the apical foramen to ensure apical patency.

A gutta-percha lateral condensation technique was used to obturate all nine experimental groups. In groups 1, 4, and 7 Roth’s 811 sealer (Roth International Ltd., Chicago IL) was used. AH26 sealer (Dentsply/Caulk) was used in groups 2, 5, and 8, and Sealapex sealer (Kerr Corporation, Romulus, MI) as used in groups 3, 6, and 9. The positive control group was obturated with gutta-percha without sealer, and the negative control group was obturated using lateral condensation of gutta-percha and Roth’s 811 sealer.

Immediately after obturation, gutta-percha was removed to a level 5 mm from the working length using a Touch ‘n Heat (Analytic Technology/Kerr). This measurement was verified using radiographs. The roots of all experimental groups and the positive control were coated with two coats of clear nail polish (Revlon) except for the apical 2 mm. The entire root and apical foramen of the negative control was completely covered with two coats of the nail polish. Using the method described by Derkson and Pashley (12) the teeth were bonded to Plexiglass blocks using cyanoacrylate, and the exposed portions of the roots were submerged in a 0.2% sodium azide solution during the time period between microleakage measurements. Microleakage was measured using the fluid
filtration method under 10 psi. The system was infused with 0.2% fluorescein dye to aid in the visualization of any leakage that occurred throughout the root canal system or cyanoacrylate interfaces. Once the system was activated under 10 psi, a 2-minute stabilization period was provided for each tooth. After this stabilization period the samples were measured for 1-minute, four times in succession at each time interval of 270 and 360 days. Measurements were averaged and converted to microliters per minute. The experiment is a 3 x 3 design with two detached control groups. The two interventions were: (a) Endodontic irrigating solutions (NaOCl, 0.12% Chlorhexidine gluconate, and saline), and (b) Endodontic obturating sealers (AH 26, Roth’s 811, and Sealapex). The results were analyzed using mixed-models repeated-measures ANOVA with Tukey’s HSD multiple comparison procedure and significance set at p<0.05. The 90- and 180-day results were analyzed in an earlier study (11).
Figure 1 Fluid Filtration Apparatus
Results

The leakage of the negative controls were all uniformly zero and the leakage of the positive controls were all immeasurably high. The 270- and 360-day observation periods were analyzed separately.

As reported in the previous paper, at the 90-day observation point, the ANOVA results showed no significant difference due to irrigation main effect (\( p = 0.9962 \)), sealant main effect (\( p = 0.7145 \)), nor the interaction (\( p = 0.5175 \)). Similarly at the 180-day observation point, the ANOVA results showed no significant difference due to the irrigation main effect (\( p = 0.3558 \)), sealer main effect (\( p = 0.3812 \)), nor the interaction (\( p = 0.7493 \)).

The full ANOVA results for the 270- and 360-day trials showed no significant difference due to irrigation main effect (\( p = 0.1315 \)), sealer main effect (\( p = 0.4248 \)), nor the interaction (\( p = 0.0557 \)). However, the three-way interaction of irrigation, sealer, and days is significant (\( p = 0.0052 \)). That is, the effects of irrigation, sealer, and days each depend on the others and so simple interpretation of any main-effect or two-way interaction is problematic. The mean leakage for each experimental condition in both Parts I and II is shown in Figure 1 and illustrates that trends across time are not parallel. While most sealer-irrigant combinations tended to leak less over time, the saline-Sealapex and saline AH26 combinations did not.
At the 270-day time interval, a significant difference emerges. At this time point, there is a significant interaction between sealer and irrigation method ($p = 0.0125$). The estimated LS mean leakage values of all irrigant-sealer combinations at 270 days are shown in Figure 2. Tukey’s HSD multiple comparison procedure indicated that the saline-Sealapex combination has significantly higher leakage than either Peridex-Sealapex or saline-Roth’s. There were no other significant differences at 270 days.

At the 360-day time interval, there was also a significant irrigation-sealer interaction ($p = 0.0300$). The estimated LS mean leakage values of all irrigant-sealer combinations at 360 days are shown in Figure 3. Tukey’s HSD multiple comparison procedure indicated that the saline-Sealapex combination has significantly higher leakage than saline-Roth’s. There were no other significant differences at 360 days.

Discussion

Chlorhexidine in the chemical form is a cationic bis-biguanide that is primarily marketed as a gluconate salt. A commercially available oral rinse contains 0.12% chlorhexidine gluconate in a base containing water, 11.6% alcohol, glycerine, flavoring agents, and saccharin. Approximately 30% of the active ingredient is retained in the oral cavity after rinsing and is slowly released into the oral fluids (13). This substantive antimicrobial activity has been identified as a potentially protective element in the canal tissues for many hours after instrumentation (14). The potential for chlorhexidine gluconate use in endodontics has been clearly demonstrated by numerous investigators (1, 2, 15-18); however there is a lack of research regarding the effects of chlorhexidine gluconate on the apical sealing ability of some common endodontic sealers.

Many investigators have studied and compared the sealing ability of different endodontic sealers. Lim and Tidmarsh (9), using an electrochemical leakage method, determined that Sealapex exhibited significantly less leakage than AH26 at 12 wk, but at 26 wk there was no significant difference. Wu et al. (19), using the fluid transport model, revealed that AH26 had a reduction in leakage over time and demonstrated significantly less leakage than Sealapex.

This study was undertaken to determine whether chlorhexidine gluconate, used as an endodontic irrigant, would adversely effect the sealing ability of three endodontic sealers.
Our study also used a fluid filtration method that allowed us to examine quantitatively the leakage of teeth over time. In contrast to previous studies, our short-term results demonstrated no significant differences in apical leakage using three irrigants (sterile saline, 5.25% sodium hypochlorite, and Peridex) and three different sealers (Roth’s 811, Sealapex, and AH26) at both 90- and 180-day observation periods. Our long-term results using the same combinations of sealers and irrigants indicated that the saline-Sealapex combination has significantly higher leakage than either Peridex-Sealapex or saline-Roth’s combinations at 270- days. At 360-day observations, our data indicated that the saline-Sealapex combination has significantly higher leakage than saline-Roth’s.

The fluid filtration method proved to be very technique-sensitive. There was a tendency for leakage to occur at the Plexiglass/cyanoacrylate interface that made it necessary to remove the old adhesive and reattach the teeth to the Plexiglass block with fresh cyanoacrylate at each observation period. Teeth were stored in closed containers with the apical root ends suspended in the 0.2% sodium azide solution and maintained in a 98.0-degree incubator between the observation periods. Because cyanoacrylate is a water-based adhesive the breakdown at the interface was expected. Teeth fractured during the reattachment process were eliminated from the study.

While both chlorhexidine gluconate and sodium hypochlorite are effective as antimicrobial agents, chlorhexidine gluconate has the possible clinical advantage of being relatively non-toxic to vital tissue (2). This could influence a decision to use
chlorhexidine gluconate in teeth with perforations, open apices, or difficult isolation cases. Another advantage of using chlorhexidine gluconate is that it could be used for patients that are allergic to sodium hypochlorite (20). The major disadvantage of using chlorhexidine gluconate as the primary endodontic irrigant is that it lacks the ability to dissolve necrotic pulp tissue.

The results of this study demonstrate significantly higher leakage from the saline-Sealapex combination than either Peridex-Sealapex or saline-Roth’s combination at 270-days, and significantly higher leakage from the saline-Sealapex combination than the saline-Roth’s combination at 360-days. These results may confirm the findings of Wu et al. (19), that Sealapex breaks down over time when in contact with fluids, thereby reducing its sealing ability unless the thickness layer of sealer was very thin (0.05 mm).

No effort was made in this study to control or measure the thickness layers of any sealer. Each sealer was mixed and handled as directed by the manufacturer. The fact that the Peridex-Sealapex combination provided significantly better seal than the saline-Sealapex combination cannot be explained. The results of this study showed that 0.12% chlorhexidine gluconate when used as an endodontic irrigant does not adversely affect the apical seal when using either Roth’s, AH 26, or Sealapex sealers.
