First-principles calculations based on density-functional theory reveal some unusual properties of BN sheet functionalized with hydrogen and fluorine. These properties differ from those of similarly functionalized graphene even though both share the same honeycomb structure. (1) Unlike graphene which undergoes a metal to insulator transition when fully hydrogenated, the band gap of the BN sheet significantly narrows when fully saturated with hydrogen. Furthermore, the band gap of the BN sheet can be tuned from 4.7 to 0.6 eV and the system can be a direct or an indirect semiconductor or even a half-metal depending on surface coverage. (2) Unlike graphene, the hydrogenation of BN sheet is endothermic. (3) Unlike graphene, BN sheet has heteroatomic composition. When codecorated with H and F, it can lead to anisotropic structures with rich electronic and magnetic properties. (4) Unlike graphene, BN sheets can be made ferromagnetic, antiferromagnetic, or magnetically degenerate depending on how the surface is functionalized. (5) The stability of magnetic coupling of functionalized BN sheet can be further modulated by applying external strain. Our study highlights the potential of functionalized BN sheets for unusual applications.

I. INTRODUCTION

Dimensionality has become an important parameter to tune the properties of materials. Currently, tremendous effort has been devoted to two-dimensional (2D) atomic-layer-based materials. One of such example is graphene1 which has many advantages compared to carbon nanotubes (CNTs) when used in polymeric composites. The covalently bonded honeycomb lattice of the graphene sheet shows high stability and exceptional properties2 such as high electron mobility even at room temperature, ambipolar effect, Klein tunneling, and anomalous quantum Hall effect. Especially, electrons in graphene sheet behave like massless Dirac fermions making the observation of several relativistic effects possible. The impressive progress in graphene research has motivated scientists to explore other 2D atomic based materials. Among them, BN sheet has become a hotly pursued system as it shares the same honeycomb lattice structure as graphene. Using a chemical-solution-derived method starting from single-crystalline hexagonal boron nitride, Han and coworkers successfully synthesized BN monatomic layer.3

Very recently, an efficient method to fabricate high-yield 2D BN sheets has been developed by using a sonication-centrifugation technique4 where milligram quantity of BN sheets are achievable and ultimately pure BN sheets can be obtained based on a highly pure precursor. The sheet thickness can be adjusted by the centrifugation speed.

The advances in experimental synthesis of BN sheet have led us to explore the properties of BN sheet by decorating its surface. Although BN sheet has similar geometry as graphene sheet, it can display different properties. For example, unlike graphite, BN layers are stable under high temperature up to 1000 K. BN sheet is semiconducting while graphene sheet is metallic. In order to open a band gap in graphene, surface modification such as hydrogenation is needed. The resulting graphene sheet5,6 has a band gap of 4.5 eV which is tunable by modifying its surface with atoms such as F.7 Similar decoration of BN sheet raises some interesting questions: (1) since the BN sheet is already semiconducting with a band gap of 4.7 eV, how would its band gap change when hydrogenated or fluorinated? (2) When half of the H atoms are removed from a fully hydrogenated graphene sheet (graphane), the resulting semihydrogenated graphene sheet (graphone) becomes ferromagnetic,8 but it is still nonmagnetic when semifluorinated. What would be the magnetic properties of semifluorinated or semifluorinated BN sheet? Is it ferromagnetic, antiferromagnetic, or nonmagnetic? (3) All C atoms in graphene sheet are equivalent with covalent bonding between them. In contrast, B and N sites in BN sheet are not equivalent. The charge transfer from B to N permits the bonding between them to be more ionic, thus the properties of semidecorated BN sheet will depend on which sites are decorated with H and/or F. How would codecoration of BN sheet with H on one side and F on the other side affect its electronic and magnetic properties?

In this paper, we have made extensive studies of the electronic structure and magnetic properties of fully decorated and semidecorated BN sheets using H and/or F atoms. We show that for a fully hydrogenated BN sheet, the energy band gap is reduced from that in pristine BN sheet. With semidecoration on different sites, BN sheet can display ferromagnetic (FM) or antiferromagnetic (AF) properties. And for semifluorinated BN sheet, contrary to what has been found in the case of BN nanotube, FM and AF states are nearly degenerated. In addition, the relative stability of FM and AF states can be further modulated by applying external strain.

II. METHODS

Our calculations are based on spin-polarized density-functional theory (DFT) using generalized gradient approxi-
III. RESULTS AND DISCUSSION

In the following, we discuss the electronic structure and properties of BN sheet when (1) fully hydrogenated, (2) semifluorinated, (3) semifluorinated, (4) under influence of external strain, and (5) semifluorinated and semifluorinated.

A. Fully hydrogenated BN sheet

Following the idea of hydrogenation of graphene sheet, we first discuss the results for a fully hydrogenated h-BN sheet (labeled as H-BN-H) which is very similar in geometry to its carbon counterpart, graphene, as shown in Fig. 1(a), where B and N atoms become $sp^3$ hybridized which distorts the planar geometry forming a zigzag configuration as C atoms do in graphene. The distance between B and N planes is found to be 0.518 Å. The hydrogen atoms are adsorbed on the top site of B and N atoms with H-B and H-N bond lengths of 1.201 and 1.036 Å, respectively. The bond length of H-B is a little larger than that of H-N bond length because of the difference in bonding. Charge analysis with Wigner-Seitz partition suggests that H atoms adsorbed on B and N are both positively charged carrying charges of 0.012 and 0.129 electrons, respectively. To study the energetics of hydrogenation, we calculated the formation energy which is defined as the energy difference between the hydrogenated BN sheet, pristine BN sheet, and H$_2$ molecules. We found that, in contrast to the graphene sheet, the hydrogenation of BN sheet is endothermic with energy of 0.195 eV/H.

The energy-band structure and partial density of state (PDOS) of H-BN-H are plotted in Fig. 1(b). It is found to be nonmagnetic with a direct band gap of 3.33 eV, which is lower than that in the pristine BN sheet, namely, 4.71 eV. The valence-band maximum (VBM) and conduction-band minimum (CBM) are both located at the $\Gamma$ point in the reciprocal space. Here we see some differences between fully hydrogenated graphene and BN sheet. Hydrogenation opens a band gap in the former while it reduces the band gap in the latter. In fact, introduction of two H atoms introduces two occupied energy bands (one in majority and one in minority band sharing the same energy). These are located just above the valence band of pristine BN sheet. Accordingly, the band gap of the system is reduced.

B. Semihydrogenated BN sheet

As stated in previous discussions, the hydrogenation of BN sheet is an endothermic process. Once fully hydrogenated, H can bind on B and N sites with the bond lengths of 1.201 and 1.036 Å, respectively, which are comparable to the bond lengths of 1.23 and 1.03 Å for the corresponding BH and NH dimers in free states. This suggests that H can strongly bind to the distorted nonplanar BN sheet. This can be understood by considering the fact that distortion changes the bonding between B and N and enhances the reactivity. Now the next question is: starting from the fully hydrogenated BN sheet, can one find a way to remove hydrogen from one side forming a semihydrogenated BN sheet? If so, how will the properties change?
ELECTRONIC AND MAGNETIC PROPERTIES OF A BN...

In graphene sheet, all the C sites are equivalent. Thus, when removing half of H atoms from a fully hydrogenated graphene sheet (graphane), we have only one option for the semihydrogenated sheet. However, in BN sheet, B and N sites are not equivalent and semihydrogenation can be accomplished by removing H from either B sites or N sites. Which is the preferred configuration? To find this, we first considered semihydrogenation by placing H on B sites, as indicated slightly above the highest occupied valence band of pristine BN sheet. The charge transfer from B to N and the orbital hybridization make electrons paired and the system is nonmagnetic. The 2p\(_e\) electrons of N atoms contribute to the highest occupied VBM while 2p\(_e\) electrons of B atoms contribute to lowest unoccupied CBM. When semihydrogenated on B sites, B atoms are covalently bonded with H atoms forming \(sp^3\) hybridization and almost no charge transfer occurs from B to N. Thus 2p\(_e\) electrons on N atoms remain unpaired. The extended p-p interaction results in a long-range magnetic coupling between 2p moments as found in graphene sheet. Conventionally, magnetic moment comes from unfilled d or f orbitals of metallic atoms. Using mean-field theory and the energy difference between FM and AF states, we can estimate the Curie temperature of H-BN by the formula \(\gamma k_B T_c/2 = E_{AF} - E_{FM}\), where \(\gamma\) is the dimension of the system and \(k_B\) is Boltzmann constant. Our estimated results are 293 and 440 K, depending on whether the system is treated as three dimensional (3D) and 2D, respectively.

Band structure and PDOS are plotted in Fig. 2(c). We find that the system is half metallic where majority-spin state remains as an indirect band-gap insulator with band gap of 5.05 eV, while minority-spin state is metallic. To visualize the magnetic property clearly, we plotted the isosurface and a two-dimensional slice of spin density. We see that the magnetism on N atoms is mainly contributed by unsaturated 2p\(_e\) orbital, which is consistent with the results obtained from PDOS. We find that one H atom adsorbed on B site introduces one occupied energy band in majority channel as well as one unoccupied energy band with slightly higher energy in the minority channel. The two energy bands are located slightly above the highest occupied valence band of pristine BN sheet. If the concentration of H atoms is increased to the level of semihydrogenation, the new induced occupied and unoccupied energy bands will be broadened due to hybridization effect. They will collapse with each other and give rise to half-metallic band structure.

For the semihydrogenation on N sites (denoted as H-NB), the optimized H-NB sheet shows that the distance between B and N planes is 0.450 Å, which is larger than that of H-BN case (0.266 Å) and smaller than that of H-BN-H case (0.518 Å). The H-N bond length of 1.083 Å is comparable to the bond length of 1.03 Å in NH dimer in a free state. Since B atom has a valence configuration of 2s\(^2\)2p\(^1\), once N sites are terminated with H, the charge transfer from B to N is diminished, leaving 2p electron spin in B site unpaired. In fact, we found that the unhydrogenated B atoms carried a magnetic moment of about 0.75\(\mu_B\), while very small net magnetic moment was found on H or N atoms. We computed total energies for three magnetic configurations (FM, AF, and NM). The AF state is found to be energetically most stable.
C. Semifluorinated BN sheet

We see from above that the electronic and magnetic properties of BN sheet can be tuned by decorating B or N sites with H atoms. In this section, we study the fluorination of BN sheet. The motivations are twofold: (1) studies have already been carried out experimentally and theoretically on fluorination of graphene,\textsuperscript{7,16} CNT,\textsuperscript{17–19} and fullerenes [C\textsubscript{60}F\textsubscript{18},\textsuperscript{20,21} C\textsubscript{60}F\textsubscript{36},\textsuperscript{22,23} C\textsubscript{60}F\textsubscript{48},\textsuperscript{23–25} C\textsubscript{60}F\textsubscript{60},\textsuperscript{26} C\textsubscript{66}F\textsubscript{34} (Ref. 27)]. It has been found that fluorination can be used to change CNT from metallic to semiconducting\textsuperscript{10} or from non-magnetic to magnetic.\textsuperscript{28} Therefore, it is highly desirable to see if fluorination of BN sheet can induce some new effects.

(2) Hydrogenation of BN sheet is found to be endothermic. One of the reasons is that the bonding in H\textsubscript{2} is strong. Since bonding in F\textsubscript{2} is weaker than in H\textsubscript{2}, an interesting question arises: is fluorination of BN sheet endothermic or exothermic? In this section, we discuss the effect of fluorination of BN sheet on electronic and magnetic properties.

Because of weak binding between F and N atoms,\textsuperscript{29} we only consider semifluorination of BN sheet in which F atoms are attached to B atoms in BN (termed as F-BN) (Fig. 4). This structure may be synthesized in fluorine plasma environment by protecting one side of BN sheet. In the optimized geometric structures, the distance between B and N planes is found to be 0.375 Å, and F-B bond length is 1.415 Å, which is a little bit larger than the BF dimer bond length of 1.263 Å in a free state.\textsuperscript{14} In contrast to that found in hydrogenation, fluorination is found to be exothermic and the formation energy is 0.645 eV/F. Again, we found that the N atoms carry a magnetic moment of about 1\(\mu_B\). Three magnetic states with their corresponding energies are given in Fig. 4(a), showing that the AF state is the most stable one and lies 0.027 and 1.114 eV lower than FM and NM states, respectively. Thus, the energy difference between AF and FM states per unit cell is 7 meV. This energy is small and comparable to that due to thermal fluctuation. Hence, we conclude that the FM and AF states are nearly degenerate. Their corresponding band structure and PDOS are plotted in Fig. 4. We see that FM state is half metallic, where the majority channel remains insulating with a band gap of 6.57 eV, and the minority channel is conducting. Analysis of PDOS shows that the magnetism on N atoms is mainly contributed by the unpaired 2\(p_z\) orbital. This can be visualized from the isosurface of spin density in Fig. 4(c). The relevant mechanism is similar to what we discussed in H-BN sheet. The binding of F atoms on B sites makes the 2\(p_z\) electrons on N sites unpaired. We also found that when two F atoms are introduced, two unoccupied energy bands are induced in the minority-spin channel just slightly above the valence band. When more F atoms are adsorbed, the system finally becomes half metallic.

For the AF state, the system becomes a direct band-gap semiconductor with a small band gap of 0.63 eV. Just above the valence band of pristine BN sheet, we note that there are four induced energy bands in the conduction manifold (two in majority and two in minority-spin channel). A large band gap exists above these two bands. The isosurface and two-dimensional slice of spin density are plotted in Fig. 4(f).
D. Applied stress on semifluorinated BN sheet

We found that magnetic properties of fluorinated BN sheet are different from that in the fluorinated BN nanotube. The latter has been found to be FM. To see if this difference is due to strain caused by curvature effects on the BN nanotube, we applied in-plane tensile and compressive stresses in the fluorinated BN sheet. For the F-BN system under tensile stress, the energy difference between AF and FM states increases with higher tension and AF is always more stable than FM state. But for the compressive stress on F-BN, we found that the energy of FM state increases slower than AF state and at 5% in-plane compression, FM state is energetically more stable than AF state by 32 meV per unit cell (Fig. 5).

E. BN sheet codecorated with H and F

As we have seen from above that hydrogenation of BN sheet is endothermic, but once the sheet is distorted, H can easily bind on B or N sites. Also, we find that fluorination is exothermic and can distort the sheet. Therefore, we can further introduce H to the semifluorinated BN sheet forming a codecorated sheet, where F atoms are attached to the B site while H atoms are attached to the N sites (labeled as F-BN-H, as shown in Fig. 6).

The optimized F-B and H-N distances are shorter than those in F-BN and H-NB sheets indicating that the bonding is stronger than that in the systems discussed above. Conse-

FIG. 6. (Color online) (a) Calculated geometric structure. (b) Band structure and PDOS of F-BN-H. (c) The charge-density difference ($\rho_{F-BN-H} - \rho_{F-BN} - \rho_H$) of F-BN-H.
fluorination of BN sheet. In Table I, we summarize the results. The main conclusions are as follows. (1) Hydrogenation is endothermic while fluorination is exothermic. (2) Our calculations show that fully decorated systems are all direct band-gap semiconductors. (3) In semidecorated systems, H-BN, F-BN, and H-NB, the unsaturated N or B atoms carry magnetic moments which are contributed mainly by 2p_\sigma orbital. H-BN and H-NB systems couple, respectively, ferromagnetically and antiferromagnetically. However, in F-BN system, the ferromagnetic and antiferromagnetic states are energetically nearly degenerate. (4) The induced energy band is located above the valence band or below the conduction band and reflects how electrons are transferred. For the H-BN and F-BN in FM state, both the systems possess half-metallicity with majority-spin channel being semiconducting while minority-spin channel being metallic. These are related to the extension of occupied and unoccupied energy bands above the valence band of pristine BN sheet. The H-NB and F-BN systems in AF state behave as semiconductors with small energy gaps. (5) The in-plane strain can be used to tune the relative stability of FM and AF configurations of the F-BN system. (6) Codecoration with H and F atoms can introduce anisotropy in charge distribution, which can be used to facilitate self-assembly under an applied electric field, making it possible to overcome the weakness of van der Waals interactions between the pristine BN sheets. (7) All surface decorations of the BN sheet reduce the energy-band gap displaying different behaviors from that in the graphene sheet. The diverse properties of decorated BN sheets have the potential for wider applications of 2D-based materials and devices.
