Caging of Ni clusters by benzene molecules and its effect on the magnetism of Ni clusters

B. K. Rao and P. Jena

Physics Department, Virginia Commonwealth University, Richmond, Virginia 23284-2000

(Received 26 July 2001; accepted 30 October 2001)

Global optimization of the geometry of small Ni clusters interacting with benzene molecules yields equilibrium structures where the Ni atoms find themselves caged between the benzene molecules. This leads to quenching of the Ni magnetic moment in most of the complexes even though the structure of the caged Ni clusters remain relatively unchanged from their otherwise free gas phase geometry. The accuracy of these predictions, based on density functional theory with generalized gradient approximation for exchange and correlation, is established by the good agreement achieved between the calculated and available experimental dissociation energies and ionization potentials.

I. INTRODUCTION

The passivation of metal clusters by organic ligands is one of the ways to prevent them from coalescing during cluster assembly. Since the interaction of the ligand atoms with the metal atoms is likely to change the properties of otherwise bare metal clusters, a fundamental understanding of this interaction is necessary for tailor-making cluster-assembled materials. With this in mind, a considerable amount of experimental work has been recently carried out on metallo-organic complexes as well as metal oxide clusters coated with organic ligands. For example, a series of experiments involving organic molecules such as benzene interacting with 3d transition metal atoms (Sc, Ti, V, Cr, Mn, Fe, Co, and Ni) in the gas phase have been carried out, thus eliminating the complicating factor associated with the role of solvents.

In particular, we focus on the work of Kaya and co-workers. These authors have measured the mass spectra, ionization potentials, reactivity, and in some restricted cases, electron affinities of transition metal–benzene complexes systematically. They observed that while the dominant peaks in the mass ion spectra of metal–benzene complexes involving the early part of the 3d-series (Mn(Bz)_m; M=Sc, Ti, V, Cr, Mn) are characterized by one excess benzene molecule for every metal atom, (m = n + 1), the number of metal atoms in Co(Bz)_m and Ni(Bz)_m can even exceed those of benzene molecules (n > m). More importantly, in Ni(Bz)_m complexes containing the maximum, m_{max} number of benzene molecules for each metal composition, n are unreactive towards NH_3 while Mg(Bz)_m (M=Sc,···,Cr) complexes with n>m are reactive. These results seem to indicate that the geometry and electronic structure of Ni(Bz)_m complexes are fundamentally different from those involving early 3d-metal atoms. No theoretical explanation of this unusual behavior of Ni–benzene complexes is available in the literature.

Several theoretical calculations have been carried out to understand the geometry, relative stability, and dissociation energy of these complexes. One of the early systematic studies in this regard is due to that of Bauschlicher and co-workers who studied 3d metal atoms adsorbed on benzene using a C_6_0 symmetry. The present authors and their collaborators have studied 3d metal atoms atop a benzene molecule using C_6_0 symmetry and those sandwiched between two benzene molecules using D_6h symmetry. Bowers and co-workers have studied larger complexes involving V and benzene. No calculations of the structure of Ni(Bz)_m (n,m > 1) exist where geometries were optimized without any symmetry constraint. In this paper we present the first fully optimized geometries of Ni(Bz)_m and Ni(Bz)_m (n=3,m=2) complexes with no symmetry constraint. The dissociation energies, ionization potentials, and magnetic moments are calculated using density functional theory with generalized gradient approximation (DFT-GGA) for exchange and correlation. The accuracy of these predicted results is established by comparing them with available experiment. In Sec. II we briefly describe the computational procedure. The results are discussed in Sec. III. A summary of our conclusions is given in Sec. IV.

II. COMPUTATIONAL PROCEDURE

The calculations were carried out using the linear combination of atomic orbitals-molecular orbital (LCAO-MO) approach. The atomic wave functions were represented by Gaussian orbitals (LANL2DZ basis). To assess the accuracy of these basis functions, we have repeated the calculations of the NiBz cluster using an all-electron triple zeta basis set with extra polarization functions (6-311G**). The total energies were calculated using the density functional theory (DFT) and generalized gradient approximation (GGA) for exchange-correlation contribution. The Becke–Perdew–Wang (commonly referred to as BPW91) form of the functional and the GAUSSIAN 98 code were used in our computations. The geometries were optimized without any symmetry constraint for different spin multiplicities. For each cluster the optimization was performed by starting from several initial structures to locate through exploration of the potential energy surface, the geometry corresponding to the
Comparisons of these two basis sets in other systems have approximately 0.2 Å, the energies agree within about 0.3 eV.

The C–C, C–H, and NiC distances obtained using the LANL2DZ basis set are, respectively, 1.44 Å, 1.09 Å, and 2.14 Å and these agree very well with the corresponding values of 1.44 Å, 1.09 Å, and 1.98 Å obtained from the 6-311G** basis set. Similarly the binding energy and the ionization potential of Ni–Bz using the 6-311G** basis are 1.54 eV and 5.78 eV while those using the LANL2DZ basis are 1.22 eV and 6.17 eV. Note that while the bond lengths agree within approximately 0.2 Å, the energies agree within about 0.3 eV. Comparisons of these two basis sets in other systems have resulted in similar conclusions. In view of the computational cost, we have decided to use the LANL2DZ basis for all the remaining calculations. The above comparison should be viewed in terms of the limitations of the predicted results.

### III. RESULTS AND DISCUSSIONS

In order to assess the accuracy of the calculated geometries and energetics of the Ni–benzene complexes we have used Ni–benzene with C$_{6v}$ geometry as a test case. We have calculated the equilibrium bond lengths, binding energy (i.e., energy needed to dissociate Ni–Bz to Ni and Bz), and the adiabatic ionization potential using the frozen core LANL2DZ basis and the all-electron 6-311G** basis sets. The C–C, C–H, and NiC distances obtained using the LANL2DZ basis are, respectively, 1.44 Å, 1.09 Å, and 2.14 Å and these agree very well with the corresponding values of 1.44 Å, 1.09 Å, and 1.98 Å obtained from the 6-311G** basis set. Similarly the binding energy and the ionization potential of Ni–Bz using the 6-311G** basis are 1.54 eV and 5.78 eV while those using the LANL2DZ basis are 1.22 eV and 6.17 eV. Note that while the bond lengths agree within approximately 0.2 Å, the energies agree within about 0.3 eV. Comparisons of these two basis sets in other systems have resulted in similar conclusions. In view of the computational cost, we have decided to use the LANL2DZ basis for all the remaining calculations. The above comparison should be viewed in terms of the limitations of the predicted results.

#### A. Geometries

In Fig. 1 we present the ground state geometries of neutral Ni$_n$(Bz)$_m$ ($n \leq 3, m \leq 2$) complexes. The corresponding geometries for the ground state of cationic complexes are shown in Fig. 2. In agreement with previous calculations, the geometries of the neutral and cationic NiBz assume a C$_{6v}$ symmetry. The geometry of Ni$_2$Bz [Fig. 1(b)] consists of a Ni$_2$ dimer with a bond length of 2.27 Å bonded to four of the carbon atoms of a slightly distorted benzene ring. Note that in Ni$_2$Bz [Fig. 1(c)], the distortions of the ring are reduced while the Ni$_3$ trimer in a nearly equilateral triangular configuration binds to all the six carbon atoms of the benzene molecule. The ground state geometry of neutral Ni(Bz)$_2$ in Fig. 1(d) is characterized by the second benzene molecule sliding on top of the Ni atom until its C–C bond lies just above it. In addition, this molecule is tilted with respect to the bottom benzene plane and is accompanied by minor changes in the C–C and C–H bond as well as C–H bond angle. In the cationic Ni(Bz)$_2^+$ complex [Fig. 2(d)] the structure approaches a more symmetric form with the two benzene planes becoming more parallel and on top of each other than in the corresponding neutral complex in Fig. 1(d). The structure of neutral Ni$_3$(Bz)$_2$ [Fig. 1(e)] is composed of a Ni$_2$ dimer with a bond length of 2.40 Å with its axis nearly parallel to the two benzene planes on either side. We recall that the calculated bond length of a pure Ni dimer is 2.13 Å. The two Ni atoms in Ni$_3$(Bz)$_2$ lie along the middle of the C–C bond. Its cationic complex Ni$_3$(Bz)$_2^+$ [Fig. 2(e)] has a similar topology as the neutral complex, but the C–C and C–H bonds and angles are distorted. This distortion nearly disappears in Ni$_3$(Bz)$_2$ complex in both neutral and cationic configurations [Fig. 1(f), Fig. 2(f)]. The Ni$_3$ cluster intercalated between the two benzene molecules forms an almost equilateral triangle with a Ni–Ni bond length of 2.45 Å in neutral complex. In the cationic complex, the structure is an isosceles triangle with bond lengths of 2.39 and 2.46 Å. Note that the calculated structure of pure Ni$_3$ cluster is a nearly equilateral triangle with a Ni–Ni bond of 2.20 Å. Thus, the structure of Ni$_3$ caged between two benzene molecules, remains essentially in the same form as in bare Ni$_3$ although with a slightly stretched bond. Note that similar behavior was found for Ni$_2$.

The spin multiplicities of all the clusters studied here, with the exception of neutral Ni$_2$(Bz), Ni$_3$(Bz), and Ni$_3$(Bz)$^+$ are reduced to their lowest possible value namely singlet if the number of electrons is even, and doublet if the number of
The ground state configuration of both Ni\textsubscript{2}(Bz)\textsuperscript{+} and Ni\textsubscript{3}(Bz)\textsuperscript{+} neutrals in the spin triplet state are, respectively, 0.19 eV and 0.42 eV lower in energy than the corresponding singlet states. In Fig. 3 we compare the geometries of the spin triplet configurations with those of the singlet states. Note that apart from a slightly more symmetric structure of the triplet states, the geometries including the bond lengths are very similar. We will return to this aspect later in the paper.

We have also studied the equilibrium geometries of some higher energy isomers of Ni\textsubscript{n}(Bz)\textsubscript{m} complexes. These structures for neutral and cationic complexes are given in Figs. 4 and 5, respectively. The energy difference between these structures and corresponding ground state geometries in Figs. 1 and 2 are listed in Figs. 4 and 5, respectively. The energies of Ni(Bz)\textsubscript{2} and Ni(Bz)\textsubscript{2}\textsuperscript{+} complexes optimized with...
structures are higher in energy compared to the ground state in Fig. 1(e) and lie, respectively, 0.88 eV, 1.51 eV, and 1.57 eV above it. Similarly, the $D_{6h}$ structure of Ni$_3$(Bz)$_3$ in Fig. 4(e) lies 4.94 eV above the ground state caged structure in Fig. 1(f). The optimized $D_{6h}$ structure of Ni$_3$(Bz)$_3$ given in Fig. 5(b) is 3.25 eV higher in energy than its corresponding ground state structure in Fig. 2(f).

The topology of the Ni$_n$(Bz)$_m$ clusters can be used to shed some qualitative understanding of their reactive properties. Although the reactivity of Co$_m$(Bz)$_n$ to NH$_3$ has been studied at some length, similar experiments involving Ni$_n$(Bz)$_m$ are lacking. Since the mass ion distributions of Co$_m$(Bz)$_n$ and Ni$_n$(Bz)$_m$ exhibit some similar features, one could argue that their chemistry is also similar to each other. Thus, in analogy with Co$_m$(Bz)$_n$, we expect Ni$_2$(Bz)$_2$ and Ni$_1$(Bz)$_3$ to react with NH$_3$ while Ni$_2$(Bz)$_3$ and Ni$_3$(Bz)$_3$ may be unreactive. The optimized structures in Figs. 1 and 2 reveal that if these clusters are exposed to NH$_3$, the metal atoms lying at the edge in the intercalating layer can be accessible for chemical bonding. Thus, these clusters will be depleted from the mass spectra if exposed to reagent molecules. This is consistent with the experimental finding in the Co$_m$(Bz)$_n$ system where clusters corresponding to $(n,m) = (1,2), (2,2),$ and $(3,2)$ are reactive towards NH$_3$. To achieve a quantitative understanding of this reactivity, theoretical studies of the optimized structures of these complexes interacting with NH$_3$ will certainly be needed. We are currently studying these systems.

B. Vertical and adiabatic ionization potential

We now discuss the vertical and adiabatic ionization potentials as well as the binding energies of neutral Ni$_n$(Bz)$_m$ complexes. The ionization potential (IP) is defined as the energy needed to remove an electron from the neutral cluster, namely,

$$\text{IP} = E(\text{Ni}_n(\text{Bz})_m) - E(\text{Ni}_{n-1}(\text{Bz})_m).$$ 

Here, $E$ is the total energy of the cluster and does not include zero point contribution. If the geometry of the ionized cluster is assumed to be that of its neutral, the corresponding ionization potential is termed vertical ionization potential (VIP). On the other hand, if the ionized cluster is allowed to relax, the resulting energy difference between the neutral and the relaxed cation is termed as the adiabatic ionization potential (AIP). The difference between VIP and AIP then provides a signature of the energy gain resulting from the structural relaxation of the cationic cluster. In Table I we list these ionization potentials and compare them with available experiments. The calculated vertical ionization potential of NiBz is 6.36 eV which agrees well with the experimental value that lies in the range of 5.99 eV–6.42 eV. Similarly, the calculated VIP of Ni(Bz)$_3$ of 6.12 eV agrees well with the experimental value of 5.86 eV. If, instead, calculations were carried out with the $D_{6h}$ structure in Fig. 4(a), the computed vertical ionization potential of Ni(Bz)$_3$ will be 4.7 eV—in disagreement with experiment. This confirms the accuracy of the ground state structure in Fig. 1(d). The energy differences between VIP and AIP in all clusters studied are less than 0.4
eV. This is because the relaxation of the geometry following ionization of all clusters is rather small. The vertical ionization potentials of all \( \text{Ni}_n(\text{Bz})_m \) complexes studied here lie in the range of 5.5–6.4 eV. For \( \text{Ni}_B\text{z} \) complexes the VIP decreases sharply from \( n = 1 \) to \( n = 2 \), while in \( \text{Ni}_{m}(\text{Bz})_2 \) complexes it increases slightly over the same range. No experimental values are available for comparison.

### C. Metal atomization and dissociation energies

Also listed in Table I are the metal atomization energies of neutral \( \text{Ni}_n(\text{Bz})_m \) complexes. We define this as the energy needed to fragment the cluster into individual nickel atoms and benzene molecules, namely,

\[
E_d(n,m) = -\{E[\text{Ni}_n(\text{Bz})_m] - nE(\text{Ni}) - mE(\text{Bz})\}.
\]

The metal atomization energy of \( \text{Ni}_B\text{z} \) is 1.22 eV. As Ni atoms are successively added, keeping the same benzene content, the metal atomization energy of \( \text{Ni}_B\text{z} \) increases by 1.93 eV for \( n = 1 \) to 2 and by 2.39 eV for \( n = 2 \) to 3. Similarly, in \( \text{Ni}_{2}(\text{Bz})_2 \) complexes, the metal atomization energy increases by 2.69 eV for \( n = 1 \) to 2 and 3.33 eV for \( n = 2 \) to 3. This systematic increase in binding either by increasing Ni content or benzene content, or both, results not only because of the interaction between metal atoms but also because of interaction between metal atoms and benzene. We should point out that the calculated atomization energies of \( \text{Ni}_n \) and \( \text{Ni}_3 \) are 2.62 eV and 5.11 eV, respectively. Note that these energies are significantly smaller than \( \text{Ni}_n(\text{Bz})_m \) complexes having the same Ni content. The strength of bonding can also be analyzed by calculating the energy needed to dissociate a \( \text{Ni}_n(\text{Bz}) \) cluster into a \( \text{Ni}_n \) cluster and a benzene molecule. The dissociation energy of \( \text{Ni}_B\text{z} \) with respect to \( \text{Ni}_2 \) and \( \text{Bz} \) is 0.47 eV while that of \( \text{Ni}_B\text{z} \) with respect to \( \text{Ni}_3 \) and \( \text{Bz} \) is 0.37 eV. The corresponding energies with 2 benzene molecules is much larger.

We now discuss the dissociation energies of neutral and cationic \( \text{Ni}_n(\text{Bz})_m \) clusters. These have been studied experimentally for the cation using collision induced dissociation as well as mobility experiments. The dissociation of these complexes can occur along different pathways where the fragment could be a benzene molecule, a metal atom or their clusters, or a smaller NiBz complex. If the parent complex is charged, one has to study which fragment carries the change. In the dissociation of \( \text{Ni}_n(\text{Bz})_m^+ \) complexes, the channels that have been studied experimentally involve

\[
\text{Ni}_n(\text{Bz})_m^+ \rightarrow \text{Ni}_n(\text{Bz})_{m-1}^+ + \text{Bz}.
\]

In this work we have evaluated the energetics of several possible dissociation channels including the one in Eq. (3) and compared the energies with experiment wherever possible.

The dissociation energies of \( \text{Ni}_B\text{z} \) and \( \text{Ni}_B\text{z}^+ \) (see Tables II and III) are, respectively, 1.22 eV and 2.57 eV and compare very well with corresponding experimental values of 0.87–1.30 eV and 2.52 eV, respectively. Note that the agreement achieved here is better than those reported earlier, which is primarily due to the improved energies of the atoms in the GAUSSIAN 98 code. The dissociation energies of \( \text{Ni}_B\text{z} \rightarrow \text{Ni}_B\text{z} + \text{Bz} \) and \( \text{Ni}_B\text{z}^+ \rightarrow \text{Ni}_B\text{z}^+ + \text{Bz} \) are, respectively, 1.40 eV and 1.91 eV. There is no experimental value of the dissociation energy of the neutral \( \text{Ni}_B\text{z} \) complex, but that for the cationic complex, \( \text{Ni}_B\text{z}^+ \) agrees well with the experimental value of 1.70 eV by Bowers and Jordan.

The dissociation of Ni\(_2\)(Bz)\(_2\) and Ni\(_3\)(Bz)\(_2\) and their cations involve different possible channels. To calculate the energies needed for this dissociation along different channels, we need the total energies of neutral Ni(Bz)\(_2\), Ni\(_2\)Bz, Ni\(_3\)Bz, and their cations. The optimized geometries of these clusters and their corresponding total energies were calculated using the same procedure as outlined previously. The results are given in Figs. 1 and 2. The corresponding total energies were used to obtain the dissociation energies given in Tables II and III. Note that the path requiring the least energy for fragmentation of Ni\(_2\)(Bz)\(_2\) involves dissociation into Ni\(_2\)Bz+Bz and that of Ni\(_3\)(Bz)\(_2\) into Ni\(_3\)Bz+Bz. There are no experimental values available for comparison of these results in Table II. The dissociation of Ni\(_2\)(Bz)\(_2\)\(^+\) into NiBz\(^+\)+NiBz requires the least energy among all possible channels. No experimental value is available for this channel, but the experimental lower limit of 2.17 eV (Ref. 32) for its dissociation into Ni\(_2\)(Bz)\(_2\)\(^+\)+Bz is consistent with our calculated energy of 2.60 eV. Similarly, the energy needed to dissociate Ni\(_3\)(Bz)\(_2\)\(^+\) to Ni\(_3\)Bz\(^+\)+Bz is also consistent with the experimental lower limit\(^{33}\) of 2.17 eV. It will be useful to have additional experimental values to compare with our predicted results in Tables II and III.

We now turn to what we consider to be one of the most interesting properties of Ni\(_n\)(Bz)\(_m\) complexes, namely their magnetic properties. In Table IV we summarize the spin multiplicities of these complexes. The ground states of all neutral Ni\(_n\)(Bz)\(_m\) clusters studied here, with the exception of Ni\(_2\)Bz and Ni\(_3\)Bz, are singlets and the net magnetic moment at the Ni site is zero. On the other hand, the magnetic moment/atom of pure Ni, Ni\(_2\), and Ni\(_3\) species are, respectively, 2.0 \(\mu_B\), 1.0 \(\mu_B\), and 0.67 \(\mu_B\). In charged Ni\(_n\)(Bz)\(_m\)\(^+\) clusters, all except the Ni\(_3\)B\(_{12}\)\(^+\) have the lowest spin multiplicity, namely doublet. The quenching of the Ni\(_n\) moment in Ni\(_n\)(Bz)\(_m\) arises due to the strong hybridization between the 3d electrons of nickel and the \(\pi\)-electrons of benzene. Experimental confirmation of this prediction is awaited. We should point out that the quenching of the magnetic moment of Ni as a consequence of hybridization has been predicted in several Ni–C structures.\(^{34}\)

**IV. CONCLUSIONS**

In summary, we have obtained geometries and total energies of neutral and cationic Ni\(_n\)(Bz)\(_m\) \((n \leq 3, m \leq 2)\) clusters corresponding to both ground and higher energy isomeric states. The ground state geometries confirm the earlier experimental speculation that benzene molecules tend to cage the Ni clusters. The good agreement we have achieved between the experimental and theoretical ionization potentials and dissociation energies give support to the ground state geometries obtained in this work. We also found that the neutral Ni cluster atoms caged by benzene molecules with the exception of Ni\(_2\)Bz and Ni\(_3\)Bz completely lose their magnetism. It will be interesting to see if this trend persists in larger Ni\(_n\)(Bz)\(_m\) complexes, and if this unexpected behavior is confined only to Ni-based organometallic systems.

**ACKNOWLEDGMENTS**

This work was supported, in part, by a grant (DEFG02-96ER45579) from the Department of Energy. The authors are thankful to Professor M. Bowers for having shared his experimental results prior to publication and for useful discussions.
