Endometriosis

W. GLENN HURT, M.D.
RAY A. WERTHEIM, M.D.

Department of Obstetrics and Gynecology, Medical College of Virginia, Health Sciences Division of Virginia Commonwealth University, Richmond, Virginia

Endometriosis is diagnosed when tissue which resembles the endometrial lining exists outside the endometrial cavity. Although first described as a pathological entity in the late 1800s, the term 'endometriosis' was not introduced until the early 1920s by Sampson. The great volume of literature which has accumulated on this topic is, by and large, a product of the 20th century.

Many theories exist as to the histogenesis of endometriosis. All may be assigned to one of three basic groups in which 1) endometrial tissue is transplanted ectopically as a result of regurgitation, metastasis, or oviduct extension, 2) endometrial tissue develops ectopically in situ from local tissues, or 3) a combination of transplantation and development in situ. Of the three groups, only the first has been documented, the other two are speculative.

Grossly, endometriosis often presents as purplish, dusky red, or brownish spots or elevated nodules surrounded by varying degrees of fibrosis and scarring. Typically it involves the peritoneal surface of the ovary or ovaries, cul-de-sac, or bladder. Less frequently the bowel, appendix, bladder, ureters, cervix, vagina, and vulva are involved. Rarely, it is reported in the umbilicus, pleura, lungs, and extremities. Transplantation into surgical incisions of the abdominal wall and perineum has been documented.

Microscopic evidence of endometriosis is not always clear-cut. One would like to see endometrial-like epithelium, glands or gland-like structures, and stroma accompanied by evidence of hemorrhage. Not infrequently a picture 'consistent with endometriosis' will present itself revealing hemosiderin, fibroblasts, and pigment-laden macrophages. However, one cannot be secure in the pathological diagnosis if it is based solely on such evidence.

Malignant degeneration occurring within areas of endometriosis is uncommon—less than 1%. When it does occur, it is seen much more frequently in the glandular component as an adenocarcinoma than in the the stromal component; rarely is the malignancy of a mixed type. Endometroid carcinoma of the ovary does not appear to be directly related in its histogenesis to endometriosis.

Clinically, endometriosis is a disease of the reproductive years. Although it is being seen more frequently in teenagers, it has never been reported to occur before the menarche. The disease may pose a problem for the perimenopausal woman.

The frequency with which endometriosis is reported to occur in a given population is highly variable. Perhaps as many as 20% to 25% of women 24-45 years old have some evidence of endometriosis recognizable at the time of laparoscopy. It is being detected with increasing frequency in blacks, historically a group thought to have a very low incidence of the disease.

The patient with endometriosis usually complains of secondary dysmenorrhea or pelvic pain, menstrual abnormalities, and frequently of infertility.

The pain is highly variable and its severity often cannot be related to the extent of the disease. Pain usually begins some years after
menarche and may be premenstrual or men­
strual in occurrence. Extensive endometriosis
may be associated with chronic pain throughout
the menstrual cycle. Sometimes the disease
causes pelvic pressure or a sense of heaviness
and fullness which the patient does not interpret
as pain. Low backache and deep dyspareunia
are usually the result of uterosacral involvement.
Rectal and bladder tenesmus occurs and cyclic
sciatica (Head sign) has been reported.
Abnormalities of menstruation consisting of
hypermenorrhea and an irregular menstrual in­
terval imply ovarian involvement. Ten percent of
patients with significant endometriosis have ep­
sodes of anovulation. As the disease is com­
monly associated with an increased incidence
of endometrial polyps, leiomyomata, and ade­
nomyosis, these conditions must also be sus­
pct as causes of abnormal menstruation.
Infertility may be the result of a number of
factors: ovarian dysfunction, kinking of the ovi­
ducts, scarring of the fimbria, uterotubal spasm,
and a decrease in coital exposure due to dyspa­
reunia and chronic pelvic discomfort. This prob­
lem becomes more perplexing, however, when
one is reminded that most patients with endo­
metriosis ovulate, few have blocked tubal lu­
mens, and many have previously borne chil­
dren.

The patient with complaints suggestive of
endometriosis may or may not have the classic
physical findings of pelvic tenderness, cul-de­
sac nodularity, organ fixation, or abnormal ad­
nexal masses. Many, with minimal endometrio­
sis, appear to offer the most complaints,
whereas others, with extensive involvement,
may appear relatively asymptomatic. There is
yet another group in which endometriosis is only
an incidental finding at the time of laparoscopy
or laparotomy.

Although the pelvic findings may confirm
the suspicion of endometriosis, the diagnosis
cannot be made unless the disease process is
visualized or biopsied. Laparoscopy has proved
invaluable in the diagnosis and management of
patients suspected of having endometriosis. In­
dications for laparoscopy are given in Table 1.
When endometriosis is encountered, diagrams
of the extent of involvement should be entered
in the patient’s medical record. The Baylor
classification of pelvic endometriosis is helpful
in documenting findings and serving as a guide
to medical and/or surgical therapy (Table 2). 3

Medical management of endometriosis is
aimed at the relief of pelvic discomfort and the
preservation of the patient’s childbearing poten­
tial. Initially, analgesics and heat may provide
relief. The patient should be advised to avoid
the continued use of narcotics and alcoholic
beverages. It is best not to undertake the med­
cal suppression of endometriosis using hor­
monal therapy unless the disease has been
documented visually or by biopsy, and the ex­
tent of involvement determined. Hormonal ther­
apy is associated with many undesirable side
effects and is expensive. Patients thought to
have the disease but who in fact do not have it
should be spared prolonged courses of hor­
monal therapy.

Current hormonal regimens employ the

**TABLE 1**

Indications for Laparoscopy

- Severe unexplained pelvic pain
- Progressively severe dysmenorrhea
- Dyspareunia, especially with deep penetration
- Metrorrhagia uncontrolled by dilatation and curettage and/or hormones
- Pelvic findings suggestive of endometriosis
- Unexplained infertility

gestogens to achieve pseudopregnancy or danazol to achieve pseudomenopause. Hormones appear to give the best results in the treatment of mild degrees of endometriotic involvement. They are capable of relieving pain and of reducing the extent of the disease to some degree; however, they are not likely to eliminate all foci of disease and thereby effect a cure.

The gestogens, combinations of estrogen and progesterone, interrupt the negative feedback within the hypothalamic-pituitary-ovarian axis at the pituitary level. Follicle stimulating hormone (FSH) and luteinizing hormone (LH) secretions are suppressed; ovarian follicular development and ovulation are inhibited, and the secretion of ovarian estrogen and progesterone is reduced. The inherent estrogenic and progestational properties of the gestogens initially stimulate endometrial growth and induce decidual change within the endometrial tissue. Subsequently, amenorrhea and gradual atrophy of the uterine and ectopic endometrial tissue results in symptomatic relief. Pseudopregnancy regimens have been reported to provide symptomatic relief in up to 94% of patients and a corrected pregnancy rate after treatment as high as 50%. The return of symptoms and the recurrence of endometriosis after therapy appear to increase progressively with the length of follow-up unless menopause ensues. The side effects of gestogen therapy include nausea, mastodynia, vaginal discharge, fluid retention, breakthrough bleeding, and on occasion, thromboembolism. Pseudopregnancy regimens should be avoided in patients with a history of thromboembolic disease and breast or endometrial carcinoma.

Danazol, a weak synthetic testosterone, has antigonadotrophic properties similar to the gestogens. It is capable of inducing a pseudomenopausal state with its associated amenorrhea and endometrial atrophy but is unassociated with many of the undesirable side effects of gestogen therapy. Danazol suppresses FSH and LH secretion and therefore inhibits follicular development, ovulation, and corpus luteum formation. Ovarian estrogen and progesterone secretion is reduced to a minimum, causing endometrial atrophy and amenorrhea. This inactivity and atrophy of ectopic endometrial tissue allows reabsorption and healing. Side effects of danazol therapy include the vasomotor symptoms of menopause, weight gain, edema, vaginal spotting, and acne. Fortunately, significant androgenic effects are rare as the usual antigonadotrophic dose required for the treatment of endometriosis is approximately one third that capable of causing masculinization in the woman. Symptomatic improvement with the danazol-pseudomenopausal regimen is reported in up to 92% of patients. Clinical improvement is noted in approximately 60% and a corrected pregnancy rate of 50% is said to exist. Unfortunately, the recurrence of symptoms is relatively high after discontinuance of therapy. As with the pseudopregnancy regimen, conception after therapy prolongs the asymptomatic interval.

Moderate involvement with endometriosis is best treated with laparoscopic minisurgery for the lysis of adhesions, freeing of the ovaries, and cauterezation of implants; a more extensive laparotomy may be required. Conservative surgery, in cases of moderate and severe involvement with endometriosis, is undertaken in an effort to correct reflux menstruation, relieve pelvic pain, and improve fertility. It consists primarily of lysis of adhesions, the excision or destruction of all discernable endometriotic implants and cysts, and is often accompanied by uterine suspension and presacral neurectomy in an effort to prevent subsequent retrofixation of the uterus and provide relief of pelvic pain. Conservative surgical approaches have been shown markedly to improve symptoms and childbearing potential. The addition of a pseudopregnancy regimen to surgery, although recommended by some, has in most cases not significantly added to the success of the operation as measured by subsequent pregnancy or reducing the need for future surgery. Approximately one quarter of patients undergoing conservative surgical therapy for endometriosis will require future operative procedures because of endometriotic involvement.

In severe cases of endometriotic involvement, “radical” surgery, such as total abdominal hysterectomy and bilateral salpingo-oophorectomy, may offer the only hope of a cure. If this is not an acceptable alternative for the particular patient, the physician should realistically think in terms of palliation rather than cure. The growth of ectopic endometrial tissue cannot be permanently eradicated as long as functioning ovarian tissue remains within the body. Castration causes the involution and

34 / HURT AND WERTHEIM: ENDOMETRIOSIS
death of active foci of endometriosis; however, the patient may still be left with fibrotic adhesions and other residua which continue as a source of chronic pain. In selected cases, it may be advisable to follow a surgical approach to the treatment of endometriosis with a pseudopregnancy or pseudomenopausal regimen for the continued suppression of residual disease.

Hormonal therapy for the surgically-induced menopause may be required. If this can be anticipated, it is best to be sure that all foci of disease are removed at the time of surgery and not to depend upon castration alone to inactivate residual disease. If all endometriosis has been removed, the patient may be started on conjugated equine estrogen. If it is thought that some endometriosis remains, it is best to delay hormonal therapy for six months or treat the patient for that period of time with medroxyprogesterone acetate; subsequently conjugated equine estrogen therapy may be instituted on a cyclic basis.
